## ABSTRACT

Many old paintings suffer from the effects of certain physicochemical phenomena, that can seriously degrade their overall visual appearance. Cleaning methods, that utilize chemical treatment substances, can not always be used, due to possible deterioration of the painting surface or reduction of the painting artistic value. Digital image processing techniques can be utilized for the purpose of restoring the original appearance of a painting, with minimal physical interaction with the painting surface. In this paper, a number of methods are presented which can yield satisfactory results. Indeed, simulation results indicate that acceptable restoration performance may be attained, despite the small size of painting surface data utilized.

## 1. INTRODUCTION

Varnish oxidation is a phenomenon that can degrade seriously the overall visual appearance of old paintings. Dirt, smoke as well as other degradations deteriorate the situation even more. The end result is that colors faint and the painting appears black. This is particularly true for church paintings, where candle smoke degrades icon colors. In most cases, this degradation can affect the artistic value of a painting. The process of removing this oxidation layer is performed by conservation experts. It is a time-consuming process which does not always promise guaranteed success. Indeed, the prevailing environmental conditions as well as the chemical properties, which are exhibited by the wide spectrum of different varnishes, make the task of selecting the appropriate cleaning process quite difficult.

In many cases, a trial and error approach is implemented, whereas in small regions ("samples") of the painting chemical cleaning substances are applied in order to select the most appropriate one, that will be subsequently utilized to clean the whole painting. Digital image processing techniques can be applied for color

restoration, aiming at obtaining an estimate of the original appearance of a painting, without extensive chemical cleaning treatment of its surface. In this context, Volterra filters have been utilized to extract the original color information, by utilizing sampled images, in the RGB color space, of certain regions of the painting, before and after cleaning [1].

Some novel approaches to this problem are presented in this paper. Let us assume that certain uniformly colored regions of the painting have been treated with cleaning chemical substances and that a digital image representation of it is available. Of course, most image acquisition systems (e.g. scanner or camera devices) produce RGB data values. However, the RGB color space does not possess perceptual uniformity. That is, actual color differences between two colors do not correlate well with perceived color differences [2]. This fact indicates that other color spaces might be more appropriate, at least for the purposes of color image processing applications. The *CIELAB* color space exhibits good correspondence between perceived and actual color differences, with the added advantage of device-independence [3].

Of course, varnish oxidation can be modeled as a degradation process. It would be best for restoration of *CIELAB* values of both the original and the corrupted image are readily available. This could be directly obtained with the aid of a spectrophotometer. However, in most cases only photographs or digital images of the painting itself are available. Thus, only RGB data are available and a color space transformation should be performed. We assume that certain painting patches are cleaned chemically, in order to obtain reference (original) color values.

The rest of this paper is as follows. In Section 2 the mathematical foundation of the restoration methods is given. Experimental results are presented in Section 3. Finally, some conclusions regarding the overall restoration performance are presented in Section 4.

## 2. RESTORATION APPROACHES

In the approaches presented in this paper, only one acquisition pass is required, provided that a number of painting patches have already been cleaned. In addition to uniform chromaticity, these samples should be representative of the colors that appear in the painting. Finally, similar colors to the ones of these clean samples should also exist in oxidized parts of the painting.

The problem can be stated as follows. Let us suppose that  $\mathbf{s}$  is the original image (unknown) and  $\mathbf{x} = \mathbf{g}(\mathbf{s}) + \mathbf{n}$  is the degraded (oxidized) one, where  $\mathbf{g}(\cdot)$  denotes the unknown degradation function and  $\mathbf{n}$  is observation noise. Let us suppose that we have  $N$  cleaned and degraded color samples  $\mathbf{x}_i$ ,  $\mathbf{s}_i$  respectively, with  $i = 1, \dots, N$ . The problem is to perform a "blind" estimation  $\hat{\mathbf{s}}$  of the inverse function  $\hat{\mathbf{s}} = \mathbf{f}(\mathbf{x})$ , based on these measurements that minimize the following approximate expression for the mean square error (MSE):

$$MSE \simeq \frac{1}{N} \sum_{n=1}^N \|\mathbf{s}_n - \hat{\mathbf{s}}_n\|^2 = \frac{1}{N} \sum_{n=1}^N (\mathbf{s}_n - \hat{\mathbf{s}}_n)^T (\mathbf{s}_n - \hat{\mathbf{s}}_n) \quad (1)$$

As it has already been mentioned above, this approach deviates from standard restoration procedures, because the degradation function is unknown. Despite the involvement of some first-order statistics, the problem is approached clearly from a deterministic point of view. That is, little or no assumptions are made about the painting surface degradation model.

In the following, the goal is the derivation of a function that can describe adequately the change in characteristics (chrominance, luminance) of the painting surface. It should be clear that limited spatial information will be utilized in order to approximate this phenomenon.

### 2.1. Linear approximation

Assume that the color of a pixel is denoted by  $\mathbf{x} = [x_1 \ x_2 \ x_3]^T$ , where  $x_1$ ,  $x_2$  and  $x_3$  correspond to the  $L^*$ ,  $a^*$  and  $b^*$  color space coordinates of the point, respectively. If  $N$  cleaned regions are available,  $N$  corresponding regions from the oxidized part of the image should be selected. Let the vectors  $\hat{\mathbf{m}}_{\mathbf{s}_i}$  and  $\hat{\mathbf{m}}_{\mathbf{x}_i}$ , with  $i = 1, \dots, N$ , represent the sample mean of the  $i$ th clean and oxidized region, respectively. For each degraded observation  $\mathbf{x}$  we are interested in obtaining an estimate  $\hat{\mathbf{s}} = \mathbf{f}(\mathbf{x})$  of the reference color  $\mathbf{s}$ .

A possible choice for this function is:

$$\mathbf{f}(\mathbf{x}) = (\mathbf{A} + \mathbf{I})\mathbf{x} \quad (2)$$

where  $\mathbf{I}$  is the  $3 \times 3$  identity matrix and  $\mathbf{A} = [\mathbf{a}_1 \ \mathbf{a}_2 \ \mathbf{a}_3]^T$  is a  $3 \times 3$  coefficient matrix. The displacement vector

$\mathbf{d} = \mathbf{s} - \mathbf{x}$  can be expressed as:

$$\mathbf{d} = \mathbf{A}\mathbf{x} \quad (3)$$

The coefficient matrix  $\mathbf{A}$  can be computed by polynomial regression, that is:

$$[d_{1i} \ d_{2i} \ \dots \ d_{Ni}]^T = \hat{\mathbf{m}}_{\mathbf{x}}^T \mathbf{a}_i \quad (4)$$

where  $d_{ij} = \hat{m}_{\mathbf{s}_j} - \hat{m}_{\mathbf{x}_j}$  and:

$$\begin{aligned} \hat{\mathbf{m}}_{\mathbf{s}} &= [\hat{\mathbf{m}}_{\mathbf{s}_1} \ \hat{\mathbf{m}}_{\mathbf{s}_2} \ \dots \ \hat{\mathbf{m}}_{\mathbf{s}_N}] \\ \hat{\mathbf{m}}_{\mathbf{x}} &= [\hat{\mathbf{m}}_{\mathbf{x}_1} \ \hat{\mathbf{m}}_{\mathbf{x}_2} \ \dots \ \hat{\mathbf{m}}_{\mathbf{x}_N}] \end{aligned} \quad (5)$$

### 2.2. White point transformation

Another approach is based on the fact that an object may look different, under different lighting conditions [4]. Assume that a clean sample and its oxidized version are viewed under the same lighting conditions. Different *CIEXYZ* (and, consequently, *CIELAB*) values would be recorded. Instead of trying to produce an estimate of the color difference for corresponding clean and oxidized samples, an assumption can be made that both of the samples have similar *CIEXYZ* values. Thus, the difference in appearance can be attributed solely to the different white points used for the color transformation required to obtain *CIELAB* values. In the discussion that follows, vectors with the index *XYZ* refer to *CIEXYZ* tristimulus values. Let  $\mathbf{s}$  denote a vector of *CIELAB* values, which correspond to a clean sample, and let  $\mathbf{x}_{XYZ}$  denote a vector that contains the tristimulus values of the corresponding oxidized sample. The mapping from one color space to the other is given by a nonlinear equation of the form:

$$\mathbf{x} = T\{\mathbf{x}_{XYZ}; \mathbf{w}_{XYZ}\} \quad (6)$$

where  $T\{\cdot; \cdot\}$  denotes the nonlinear transformation from *CIEXYZ* to *CIELAB* and  $\mathbf{w}_{XYZ}$  is the white point tristimulus values vector. Thus, a white point vector  $\mathbf{w}_{XYZ}$  should be determined which, after being substituted into equation (6), should yield an estimate of the clean sample, that is:

$$\hat{\mathbf{s}} = T\{\mathbf{x}_{XYZ}; \mathbf{w}_{XYZ}\} \quad (7)$$

Given the sample mean vectors  $\hat{\mathbf{m}}_{\mathbf{x}_{XYZ}}$  of the oxidized samples, the error can be expressed as:

$$\mathbf{e} = \hat{\mathbf{m}}_{\mathbf{s}} - T\{\hat{\mathbf{m}}_{\mathbf{x}_{XYZ}}; \mathbf{w}_{XYZ}\} \quad (8)$$

Since the mean square error  $E[\mathbf{e}^T \mathbf{e}]$  can not be estimated, the instantaneous error function  $\mathcal{E} = \text{tr}(\mathbf{e}^T \mathbf{e})$  can be minimized with respect to  $\mathbf{w}_{XYZ}$ , to yield a solution for the white point vector. Although this is a

sub-optimal solution, it can yield satisfactory results, with little computational overhead.

White point transformation is extensively used in calibration problems [3]. Since the white point contains information about the spectral qualities of an illuminant, it may model more accurately the degradation process, compared to the other methods presented. Furthermore, only three parameters should be estimated, which can lead to fast implementations, despite the fact that the transformation  $T\{\cdot; \cdot\}$  is nonlinear; lookup tables can be used for this purpose.

### 2.3. RBF approximation

Radial basis functions networks have been used successfully as universal approximators [5, 6]. An arbitrary mapping  $f : \mathcal{R}^p \Rightarrow \mathcal{R}$  can be approximated as follows:

$$f(\mathbf{x}) \simeq \sum_{m=1}^M w_m \phi(\|\mathbf{x} - \mathbf{t}_m\|) \quad (9)$$

where  $\{\phi(\|\mathbf{x} - \mathbf{t}_m\|) | m = 1, \dots, M\}$  is a set of  $M$  arbitrary functions, which are known as *radial basis functions*, with corresponding centers  $\mathbf{t}_m$  and weights  $w_m$ . Of course, if the unknown function is a mapping of the form  $f : \mathcal{R}^p \Rightarrow \mathcal{R}^q$ , equation (9) can be utilized to perform approximation on each one of the  $q$  dimensions separately.

Let  $\phi(\cdot)$  denote the non-normalized Gaussian function, i.e.:

$$\phi(\|\mathbf{x} - \mathbf{t}_m\|) = g(\mathbf{x}; \mathbf{t}_m, \Sigma_m^{-1}) \quad (10)$$

where  $\Sigma_m^{-1}$  represents the inverse covariance matrix of the  $m$ th Gaussian and:

$$g(\mathbf{x}; \mathbf{t}_m, \Sigma_m^{-1}) = \exp \left\{ -\frac{1}{2} (\mathbf{x} - \mathbf{t}_m)^T \Sigma_m^{-1} (\mathbf{x} - \mathbf{t}_m) \right\} \quad (11)$$

Our goal, is the RBF approximation of the unknown function  $\mathbf{f} : \mathcal{R}^3 \Rightarrow \mathcal{R}^3$ , where it is known that:

$$\mathbf{f}(\hat{\mathbf{m}}_{\mathbf{x}_n}) = \hat{\mathbf{m}}_{\mathbf{s}_n} - \hat{\mathbf{m}}_{\mathbf{x}_n}, \quad n = 1, \dots, N \quad (12)$$

The function  $\mathbf{f}$  can also be written as:

$$\mathbf{f}(\mathbf{x}) = [f^{(1)}(\mathbf{x}) \quad f^{(2)}(\mathbf{x}) \quad f^{(3)}(\mathbf{x})]^T \quad (13)$$

where  $f^{(i)}$ ,  $i = 1, 2, 3$  is the  $i$ th color component of  $\mathbf{f}$ . Thus:

$$f^{(i)}(\mathbf{x}) \simeq \sum_{m=1}^M w_m^{(i)} g(\mathbf{x}; \mathbf{t}_m^{(i)}, \Sigma_m^{(i)-1}), \quad i = 1, 2, 3 \quad (14)$$

where the parameters of  $M$  Gaussian functions should be estimated, for each one of the three color components. Estimation was carried out by a gradient descent

algorithm, in order to minimize the total squared error [5]. If the data set size  $N$  is large, the computational requirements can be greatly reduced, if the inverse covariance matrix  $\Sigma_m^{(i)-1}$  takes a diagonal form. If the computational cost is still high, the inverse covariance matrix can be set equal to  $1/\sigma_m^{(i)2} \mathbf{I}$ , where  $1/\sigma_m^{(i)2}$  is the variance of the  $m$ th Gaussian function for the  $i$ th color component. It should be evident that these simplifications may limit the overall network restoration performance.

### 3. SIMULATION RESULTS

Simulations were carried out on a painting which was chemically cleaned on its right half. Regions of the cleaned and oxidized parts are depicted in Figures 1(a) and (b), respectively. Five regions on each part were selected, with sizes ranging from  $5 \times 5$  to  $16 \times 16$  points, depending on the uniformity of the sample. Sample mean values of each region were estimated and consequently utilized to restore the oxidized image, with the methods described in Section 2.

Results of the linear approximation and white point transformation methods are shown in Figures 2(a) and (b), respectively. In the RBF approach either one or two Gaussians per color channel were used to approximate the displacement in the CIELAB color space. An estimate of the mean square error  $E[(\hat{\mathbf{m}}_{\mathbf{s}} - \hat{\mathbf{m}}_{\mathbf{s}})^T (\hat{\mathbf{m}}_{\mathbf{s}} - \hat{\mathbf{m}}_{\mathbf{s}})]$  was used as a quantitative criterion for assessing color restoration performance. Results are summarized in Table 1. Subjective comparison indicated satisfactory performance, for the white point and linear approximation methods, with the former slightly outperforming the latter, as can be seen by comparing Fig. 2(a)-(b) with Fig. 1(a).

Table 1: Comparison of MSE for the presented methods.

Method	MSE
Linear approximation	93.21
White point	190.37
RBF (one Gaussian per channel)	126.46
RBF (two Gaussians per channel)	88.30

The fact that, subjectively, restoration performance does not correlate well with the figures of Table 1 may seem at variance with the claim of good perceptual uniformity of the CIELAB color space. However, these figures do not reveal the overfitting characteristics of each method. Thus, the RBF networks used approximated quite well the unknown function at the points

of the data set, but could not interpolate satisfactorily. This is not a shortcoming of RBF networks, but rather a consequence of the small data set size used in this experiment. On the other hand, white point transformation and linear approximation yielded good approximation and interpolation performance, due to the underlying "smoothing" nature of each method. Additionally, computational requirements of these two methods is low.

The effectiveness of the presented methods, was found to be strongly dependent on the size of the data used, as well as the size of the color space region they occupied. Of these two factors, the latter one is of the highest significance, because if the gamut covered by the available samples is very limited, poor restoration performance will be obtained, regardless of the number of samples used.

#### 4. CONCLUSIONS

This paper presented a number of digital restoration techniques for old paintings, which can be used to recover the original painting appearance with little physical manipulation of the painting surface. Despite the apparent simplicity of these methods, simulations performed on a number of different paintings indicated that satisfactory results can be obtained. In addition to the advantages mentioned above, the small computational requirements can contribute to the overall usefulness of these methods.

#### 5. ACKNOWLEDGEMENTS

The authors would like to thank Mr. I. Tavlakis and Mr. C. Lotsopoulos of the 10th Eforate of Byzantine Antiquities, Thessaloniki, Greece, for the photographic material used in these simulations.
